**Abstract** *Objective:* Pulmonary hypertension is a characteristic feature of acute respiratory distress syndrome (ARDS) and contributes to mortality. Administration of sildenafil in ambulatory patients with pulmonary hypertension improves oxygenation and ameliorates pulmonary hypertension. Our aim was to determine whether sildenafil is beneficial for patients with ARDS. *Design:* Prospective, open-label, multicenter, interventional cohort study. *Setting:* Medical-surgical ICU of two university hospitals. *Patients:* Ten consecutive patients meeting the NAECC criteria for ARDS. *Interventions:* A single dose

of 50 mg sildenafil citrate administered via a nasogastric tube. *Main results:* Administration of sildenafil in patients with ARDS decreased mean pulmonary arterial pressure from 25 to 22 mmHg ( $P = 0.022$ ) and pulmonary artery occlusion pressure from 16 to 13 mmHg ( $P = 0.049$ ). Systemic mean arterial pressures were markedly decreased from 81 to 75 mmHg ( $P = 0.005$ ). Sildenafil did not improve pulmonary arterial oxygen tension, but resulted in a further increase in the shunt fraction. *Conclusion:* Although sildenafil reduced pulmonary arterial pressures during ARDS, the increased shunt fraction and decreased arterial oxygenation render it unsuitable for the treatment of patients with ARDS.

*Conclusion:* Although sildenafil reduced pulmonary arterial pressures during ARDS, the increased shunt fraction and decreased arterial oxygenation render it unsuitable for the treatment of patients with ARDS.

## Introduction

With an incidence of 24 per 100,000 in The Netherlands, acute respiratory distress syndrome (ARDS) is a common cause of respiratory insufficiency requiring mechanical ventilation and admission to an intensive care unit (ICU) [1]. Both direct (e.g., pneumonia, inhalation injury) and indirect lung injury (e.g., sepsis, acute pancreatitis)

can induce ARDS [2], which is characterized by pulmonary edema (resulting from increased vascular permeability), atelectasis and a ventilation-perfusion mismatch. As a result, impaired gas exchange and hypoxemia develop. Due to hypoxia, the pulmonary arteries constrict, a phenomenon known as hypoxic pulmonary vasoconstriction [3]. Thrombo-embolic occlusions in the pulmonary microvasculature [4], increased production of

vasoconstrictive agents such as endothelin-1 [5] and thromboxane A2 [6], and pulmonary edema further augment pulmonary hypertension, which is a hallmark of ARDS [7]. The presence of pulmonary hypertension contributes to mortality [8]. Current treatment of ARDS is supportive. Specific therapeutic strategies are lacking.

Inhalation of nitric oxide (NO) dilates the pulmonary vasculature and enhances perfusion to ventilated lung regions, thereby improving oxygenation in patients with ARDS [9, 10]. However, NO inhalation as an adjunctive therapy in ARDS is controversial, since a considerable number of patients are unresponsive, and NO also has adverse effects, including renal dysfunction [11, 12].

Impaired vasoreactivity is likely to explain unresponsiveness to inhaled NO. Under physiological conditions, NO initiates the conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP) in pulmonary endothelial cells. Activation of cGMP-dependent protein kinases induces relaxation of smooth muscle cells and thus vasodilation. A family of enzymes called phosphodiesterases (PDE) inactivates cGMP by converting it to GMP [13]. During sepsis, pulmonary cGMP release may be impaired, as suggested in an animal model of endotoxemia, thereby accounting for the pulmonary vasounresponsiveness to NO [14]. Additionally, increased PDE activity may contribute to enhanced degradation of cGMP [15, 16]. Inhibition of PDE may therefore improve or even replace inhalational NO therapy in ARDS. In accordance, previous animal studies have demonstrated beneficial effects of PDE inhibitors in experimental ARDS by attenuating endotoxin-induced vasomotor dysfunction [17–19]. Besides influencing vasoreactivity, PDE inhibitors also have antiinflammatory properties, decreasing pulmonary edema, neutrophil infiltration, reactive oxygen species and levels of proinflammatory mediators in experimental acute lung injury [17–19]. These preclinical results suggest that inhibiting PDE may be a potential therapeutic target in ARDS.

Sildenafil selectively inhibits the isoenzyme PDE type 5 (PDE5), which is specific for cGMP [20]. It has been demonstrated that sildenafil increases exercise capacity during severe hypoxia in healthy volunteers [21] and improves gas exchange in patients with pulmonary hypertension [22] by selectively dilating arteries in well-ventilated areas of the lung [23]. We hypothesized that sildenafil administered to patients with ARDS would improve hypoxemia by regulation of vascular tone, thereby decreasing the shunt fraction.

## Materials and methods

### Patients

This prospective, interventional cohort study was approved by the Ethics Committee of the VU University

Medical Center. Written informed consent was obtained from the patients' next of kin. We enrolled ten patients within 1 week after establishing the diagnosis of ARDS; they were older than 18 years and admitted to the mixed medical/surgical ICUs of two university hospitals. ARDS was diagnosed according to the North American European Consensus Conference (NAECC) definition of ARDS [24]: partial arterial oxygen tension/fraction of inspired oxygen ( $\text{PaO}_2/\text{FiO}_2$ ) (P/F) ratio of less than 200 mmHg, bilateral consolidations on a chest X-ray and the absence of hydrostatic pulmonary edema, which was defined as a pulmonary artery occlusion pressure (PAOP)  $\leq 18$  mmHg. In addition, a risk factor associated with ARDS had to be present. We excluded patients with coronary artery disease, bilateral pneumonia (patients with an initial presentation of bilateral infiltrates), pre-existent lung fibrosis and hepatic insufficiency, as well as patients who were treated with nitrates, other PDE inhibitors, prostacyclins or more than 300 mg of hydrocortisone (or its equivalent of other steroids) per day. Bilateral pneumonia and lung fibrosis were exclusion criteria because of a presumed absence of vasoreactivity. We also excluded patients in whom nasogastric feeding (i.e., administration of medication) was not possible because of an underlying condition.

### Study protocol

Demographics, reason for admission to the ICU and medical history were taken from the chart. To assess disease severity, the Acute Physiology and Chronic Health Evaluation (APACHE II) score was calculated using the worst variables in a 24-h timeframe preceding enrollment [25]. When not already in place, a pulmonary artery catheter was inserted. In all patients, central venous pressure (CVP), pulmonary arterial pressure (PAP) and cardiac output (CO) were measured by a continuous cardiac output monitoring balloon-tip thermodilution pulmonary artery catheter (Baxter Edwards Critical Care, Irvine, CA) inserted via the internal jugular or subclavian vein. Pulmonary artery occlusion pressure (PAOP) was obtained from graphic recordings at end-expiration at the level of the heart without discontinuation of PEEP. All pressures were obtained after calibration, zeroing to atmosphere and using the midchest level as reference. Arterial blood pressure was continuously monitored with an intraarterial catheter. Hemodynamic variables were recorded by a patient data monitoring system.

One tablet of 50 mg of sildenafil was ground and dissolved in 20 ml of 0.9% NaCl. After baseline measurements ( $t = 0$ ), the ground sildenafil was administered as a single dose through the nasogastric tube. Hemodynamic variables were recorded at  $t = 30, 60, 90, 120, 150, 180, 210, 240$  and 360 min after the sildenafil was administered. At the same time points, arterial blood was

drawn to determine the levels of sildenafil and desmethylsildenafil. Blood gas analysis of both arterial and mixed venous blood was performed (Rapid Lab 865, Bayer Diagnostics, Dublin, Ireland). The shunt fraction ( $Q_s/Q_t$ ) was calculated using a standard formula,  $Q_s/Q_t = (CcO_2 - CaO_2)/(CcO_2 - CvO_2)$ . Ideally, ventilator settings were not changed, and dosages of vasopressors were not increased unless deemed necessary by the discretion of the treating physician during the 6 h of monitoring.

### Measurements of sildenafil levels

Serum concentrations of sildenafil and its metabolite desmethylsildenafil were measured using a validated liquid-gas chromatography mass-spectrometry method [26]. The calibration curve exhibited a linear range of 0.05–625 ng/ml with a 2-ng/ml limit for detection for sildenafil and a range of 0.05–280 ng/ml for desmethylsildenafil with a 3-ng/ml detection limit. The intra- and inter-day precision was within 6% for both compounds. Intra- and inter-day accuracy ranged from 92–103%.

### Statistical analysis

All data are summarized as median (range) or absolute numbers where appropriate. Measurements were compared to  $t = 0$  using the Wilcoxon signed rank test. The Spearman correlation coefficient was used to express relations using baseline and  $t = 30$  min. A  $P$  value  $<0.05$  was considered statistically significant. Statistical analysis was performed using SPSS 14.0 (SPSS, Chicago, IL) and Prism 5.0 (GraphPad Software, San Diego, CA).

## Results

Between 1 December 2005 and 1 December 2007, 21 ARDS patients were assessed for eligibility. Eleven patients were excluded: three were treated with another PDE inhibitor (enoximone), three had contraindications to enteral medications, and one patient suffered from pulmonary hemorrhage and was excluded for safety reasons. In three patients, consent was not provided. One patient was excluded after enrollment because findings on a CT scan performed on the day after the study protocol had been carried out rendered him ineligible. The radiological images indicated atelectasis, not ARDS.

Patient characteristics and baseline hemodynamic and respiratory parameters are displayed in Table 1. Sepsis and pneumonia were the most frequent causes of ARDS. All patients had severe pulmonary injury with pulmonary hypertension and an increased pulmonary shunt fraction. The ICU mortality rate was 10%.

**Table 1** Baseline measurements

Data are median (range) or absolute numbers: *APACHE* Acute Physiology and Chronic Health Evaluation; *CABG* coronary artery bypass grafting; *AAA* abdominal aortic aneurysm; *MAP* mean arterial pressure; *CVP* central venous pressure; *MPAP* mean pulmonary artery pressure; *PAOP* pulmonary artery occlusion pressure; *CO* cardiac output; *CI* cardiac index; *SVRI* systemic vascular resistance index; *PVRI* pulmonary vascular resistance index; *PEEP* positive end expiratory pressure; *SvO<sub>2</sub>* mixed venous saturation;  $Q_s/Q_t$  shunt fraction

### Effects on hemodynamic parameters

All hemodynamic effects were most apparent after 30 min. The mean pulmonary arterial pressure (MPAP) declined after sildenafil from 25 (23–32) mmHg at baseline to 22 (18–26) mmHg at  $t = 30$  and remained at this level until  $t = 180$  ( $P \leq 0.022$ ) (Fig. 1). The PAOP decreased from 16 (8–18) mmHg at baseline to 13 (8–18) mmHg at  $t = 30$  ( $P = 0.049$ ) and declined further to 12.5 (7–21) mmHg at  $t = 60$  ( $P = 0.027$ ). Sildenafil induced vasodilation that was not selective for the pulmonary vasculature, but decreased the systemic mean arterial pressure (MAP) from 81 (68–115) to 75 (66–98) mmHg at  $t = 30$  ( $P = 0.005$ ) and remained below baseline levels for 3.5 h (Fig. 1). In four of the seven patients requiring vasopressors, the dose was increased to maintain a mean arterial pressure of at least 65 mmHg. This typically occurred 30–60 min after sildenafil administration. Sildenafil had a rapid effect on the systemic vascular resistance index (SVRI), decreasing from 1,688 (1,058–2,425) dyne\*s/cm<sup>5</sup> at baseline to 1,400 (917–1,986)

**Fig. 1** Boxplot of hemodynamic variables during the study period displayed as median, interquartile range (box) and range (whiskers). An asterisk indicates statistically significant change as compared to  $t = 0$  (Wilcoxon signed ranks test)

dyne\* $\text{s}/\text{cm}^5$  at  $t = 30$  ( $P = 0.012$ ). The pulmonary vascular resistance index (PVRI) declined from 215 (139–478) dyne\* $\text{s}/\text{cm}^5$  at baseline to 170 (71–418) dyne\* $\text{s}/\text{cm}^5$  only after 90 min to remain at this level until  $t = 210$  ( $P \leq 0.047$ ). The cardiac index (CI) was 3.4 (2.7–5.4) at baseline, which did not change over time (at  $t = 30$ , CI was 3.7 (2.6–5.6) and at  $t = 90$ : 3.9 (2.1–5.5), NS). The left ventricular stroke work index was not affected; however, the right ventricular stroke work index decreased ( $P \leq 0.038$ ). The ratios of PVRI to SVRI and of MPAP to MAP did not change over time.

#### Effects on respiratory parameters

Sildenafil administration tended to decrease  $\text{PaO}_2$  from 87 (72–100) mmHg at baseline to 70 (54–131) mmHg at  $t = 30$  ( $P = 0.074$ ), slowly returning to baseline level after 210 min. The P/F-ratio decreased concordantly from

144 (122–200) at baseline to 115 (77–218) at  $t = 30$  ( $P = 0.074$ ), returning to baseline at  $t = 150$ . The levels of PEEP and  $\text{FiO}_2$  were not changed during the observation period. Simultaneously with the decrement of  $\text{PaO}_2$ , the shunt fraction increased from 24 (18–31)% to 31 (21–42)% ( $P \leq 0.037$ ), returning to baseline at  $t = 120$  (Fig. 2). The alveolo-arterial (A-a) gradient was not significantly affected (data not shown). Sildenafil did not alter levels of  $\text{PaCO}_2$  (data not shown). There was no statistically significant correlation between decrease in shunt fraction and decrease in MAP, nor between decrease in shunt fraction and decrease in MPAP.

#### Levels of sildenafil

The maximum plasma concentration ( $C_{\text{max}}$ ) of sildenafil was reached between  $t = 30$  and  $t = 120$ , and ranged from 107 to 975 ng/ml. The  $C_{\text{max}}$  of desmethylsildenafil,

**Fig. 2** Boxplot of shunt fraction during the study period displayed as median, interquartile range (*box*) and range (*whiskers*). An *asterisk* indicates statistically significant change as compared to  $t = 0$  (Wilcoxon signed ranks test)

the active metabolite of sildenafil, was found to be between  $t = 30$  and  $t = 60$ , and varied between 23 and 191 ng/ml. Correlation coefficients were calculated for the relation between sildenafil/desmethylsildenafil plasma concentrations at  $t = 30$  and MPAP, PAOP, MAP and P/F ratio (Fig. 3, see electronic supplement). However, neither an increase in  $C_{\max}$  of sildenafil nor an increase in  $C_{\max}$  of desmethylsildenafil correlated significantly with a decrease in the MPAP, PAOP, MAP or P/F-ratio.

## Discussion

In this study, we evaluated the effect of 50 mg of sildenafil administered as a single dose on pulmonary vascular tone and oxygenation in patients with ARDS. The major findings of the study were that sildenafil resulted in attenuation of pulmonary arterial pressures and pulmonary vascular resistance, and to a lesser degree of systemic arterial pressures and resistance. However, the observed profound increase in shunt fraction, as well as a marked decrease of  $\text{PaO}_2$ , may render sildenafil unsuitable for the treatment of ARDS.

The reductions of pulmonary arterial pressures and vascular resistance are in line with previous studies evaluating the effect of sildenafil on ambulatory patients with idiopathic pulmonary hypertension or pulmonary hypertension due to lung fibrosis. However, in these studies, reducing pulmonary hypertension was accompanied by an increase in exercise capacity or elevated  $\text{PaO}_2$  [22, 23, 27]. This increase in  $\text{PaO}_2$  was explained by an effect called preferential vasodilation in which sildenafil is thought to selectively cause vasodilation in the lung, emphasized by a decrease in the ratio of the pulmonary to systemic vascular resistance index [22]. In contrast, in our study, sildenafil decreased both pulmonary and arterial

pressure and resistance, without affecting the ratio of the pulmonary to systemic vascular resistance index or the ratio of the pulmonary to systemic arterial pressure. In other words, we did not find preferential vasodilation, which may explain the deterioration in shunt fraction and  $\text{PaO}_2$ . An explanation for these contrasting results may be the duration of disease. Sildenafil-induced preferential vasodilation was observed in patients with pulmonary hypertension due to chronic pulmonary fibrosis and hence chronic hypoxia [23]. Chronic hypoxia not only results in vasoconstriction, but also leads to vascular remodeling with thickening of the medial layer, eventually even obliterating the endovascular lumen [28]. Once medial thickening has occurred, the vasoreactivity in diseased lung areas is restricted [29], which may allow for preferential vasodilation in well-ventilated areas, thereby decreasing the shunt fraction. In contrast, in ARDS, duration of disease was less than 7 days. This time span does not allow for intimal thickening to occur. In this study, sildenafil may have resulted in general pulmonary vasodilation, increasing blood flow through both well-ventilated as well as hypoventilated (consolidated) areas, thereby reducing hypoxic vasoconstriction and increasing the shunt fraction, which in turn resulted in a lower oxygenation. Impaired vasoreactivity in chronic pulmonary hypertension as opposed to normal vasoreactivity in acute pulmonary hypertension (i.e., ARDS) may be the discriminating factor in the effect of sildenafil on oxygenation.

A compromised pulmonary blood flow may have contributed to the deterioration of oxygenation. Although both pulmonary blood pressure and pulmonary resistance decreased after sildenafil administration, we did not assess the net effect of these parameters on pulmonary blood flow. However, the clearance of  $\text{CO}_2$  was not affected, rendering this hypothesis unlikely. Notably, most of the patients were on vasopressor therapy, which may have rendered these patients at increased risk of an increasing shunt fraction after sildenafil administration. Although the effect of sildenafil on worsening of oxygenation or shunt fraction was the same in patients treated with vasopressor therapy compared to those without vasopressors, the number of patients was too small to draw conclusions about the applicability of sildenafil in specific patient groups.

Right ventricular dysfunction is a common finding in ARDS [30], contributing to prolonged mechanical ventilation [31] and to mortality [32]. It has been postulated that right ventricular failure during ARDS should prompt adjustments to ventilatory settings [33, 34], including prone positioning [35]. As sildenafil decreased right ventricular afterload in this study, thereby decreasing the right ventricular stroke work index, this compound may be an alternative strategy for ARDS patients for whom right ventricular failure is thought to contribute to a detrimental course. It should be noted that we included only

patients who strictly met the NAECC criteria for ARDS, including a pulmonary artery occlusion wedge pressure of <18 mmHg. It can be hypothesized that sildenafil may benefit ARDS patients with more severe pulmonary hypertension and concomitant higher pulmonary resistance by reducing right ventricular afterload and hence increasing right ventricular function.

In several studies with ambulatory patients, sildenafil did not have an effect on systemic arterial blood pressure [22, 23]. In our study, however, MAP decreased markedly after 50 mg of sildenafil together with a reduced SVRI. This effect may be attributed to the fact that seven out of ten patients required vasopressor support, four because of sepsis. During sepsis, increased NO release leads to vasodilation [36]. Increased levels of NO may lead to elevated levels of cGMP in the systemic circulation, which are not being degraded because of PDE inhibition by sildenafil. As a consequence, this may lead to more overt vasodilation in critically ill or septic patients when compared to ambulatory patients.

We did not find a correlation between hemodynamic or respiratory changes and the plasma concentrations of sildenafil or desmethylsildenafil. Although impaired gastric voiding was an exclusion criterion, we cannot rule out intestinal malabsorption. However, as sildenafil resulted in distinct hemodynamic and respiratory effects, malabsorption probably did not account for the absence of a correlation between effects and drug levels in this study. Rather, the sample size may have been too small to account for the great variability in pharmacodynamic properties of drugs generally found in critically ill patients [37, 38].

## Implications of the study

Although levels of PO<sub>2</sub> have not been associated with adverse outcome in ARDS, it can be hypothesized that prolonged administration of sildenafil may prolong the need of ventilatory support when oxygenation levels are targeted. Results of the study do not justify the use of sildenafil to improve oxygenation. In patients in whom right ventricular dysfunction is a therapeutic target, sildenafil may be of use. The effect of sildenafil on mortality in ARDS patients with right ventricular failure, however, remains to be determined.

## Conclusion

Administration of sildenafil to patients with ARDS ameliorates pulmonary hypertension, thereby decreasing right ventricular afterload, but has deleterious effects on shunt fraction, oxygenation and systemic blood pressure. In spite of the promising features of sildenafil found in preclinical studies, results of this study do not justify a routine place for sildenafil in the treatment of ARDS patients. Whether sildenafil may be beneficial in ARDS patients with more severe pulmonary hypertension remains to be determined.
